

Named/Typed Tensors: Brief Overview

December 10, 2020

Most papers about neural networks use the notation of vectors and matrices from applied linear algebra. This notation works well with vector spaces, but is ill suited for describing neural networks that operate on tensors with many different axes. Consider the following equation (Vaswani et al., 2017):

$$\text{Attention}(Q, K, V) = \text{softmax} \left(\frac{QK^\top}{\sqrt{d_k}} \right) V. \quad (1)$$

where Q , K , and V are sequences of query, key, and value vectors packed into matrices. Does the product QK^\top sum over the sequence, or over the query/key features? We would need to know the sizes of Q , K , and V to know that it's taken over the query/key features. Is the softmax taken over the query sequence or the key sequence? The usual notation doesn't even offer a way to answer this question. With multiple attention heads, the notation becomes more complicated and leaves more questions unanswered. With multiple sentences in a minibatch, the notation becomes more complicated still, and most papers wisely leave this detail out. As a preview, in our notation the above equation becomes

$$\text{Attention}(Q^{\text{key}}, K^{\text{seq, key}}, V^{\text{seq}}) = \text{softmax} \left(\frac{Q \cdot_{\text{key}} K}{\sqrt{|\text{key}|}} \right) \cdot_{\text{seq}} V \quad (2)$$

making it unambiguous the types of the tensors, and which axis each operation applies to. The same equation works *unchanged* when we let Q be a sequence of vectors in \mathbb{R}^{key} rather than a single vector and make the values in V be vectors rather than scalar. It also extends to multiple heads and minibatching.

We now explain our notation using a running example. Consider an image that is modeled as an order-three tensor I that maps a triple (x, y, c) into a real number corresponding to the intensity of the channel $c \in \{\text{'R'}, 'G', 'B'}\}$ at the pixel (x, y) . In our notation we write this as $I \in \mathbb{R}^{\text{width, height, channel}}$. The *type* of I is denoted as $\{\text{width, height, channel}\}$ and we will sometimes use superscripts such as $I^{\text{width, height, channel}}$ to remind the reader of it. If x, y, c are known to be indices into the **width**, **height**, **channel** axes respectively, then we can simply write $I_{x,y,c}$ for the corresponding element of I . Order here does not matter and $I_{x,y,c} = I_{y,x,c} = I_{c,x,y}$ etc. If x, y, c do not have such types (e.g., if they are simply integers) then we need to *explicitly cast* them into these types by writing $I_{\text{width}[x], \text{height}[y], \text{channel}[c]}$. If we provide fewer indices than the number of axes in I then the result is the restriction of the tensor to these values. For example, $I_{\text{channel}[\text{'B'}]}$ is the $\{\text{width, height}\}$ tensor for which every (x, y) coordinate is the intensity of the blue channel at the (x, y) pixel. We can also write this as $I_{\text{channel}=\text{'B'}}$.

By specifying axes, we can use notation such as $\text{mean}_{\text{channel}}(I)$ to denote the $\{\text{width, height}\}$ type tensor where each pixel location (x, y) contains the mean pixel intensity across the **channel** axis. In contrast, $\text{mean}_{\text{width, height}}(I)$ denotes the $\{\text{channel}\}$ type tensor that contains the average RGB values across all pixels. The same logic extends to any operation on tensors. Consider the “90 degree rotation” operation ROT that takes a tensor $A \in \mathbb{R}^{\text{width, height}}$ and maps it to the tensor $B \in \mathbb{R}^{\text{width, height}}$ such that for every (x, y) pair of coordinates, $B_{x,y} = A_{y,x}$. In our notation we write this as follows:

$$ROT(A^{\text{width,height}}) = B^{\text{width,height}} \quad (3)$$

where

$$B_{\text{width}[y], \text{height}[x]} = A_{x,y} \quad \text{For every } (x, y) \in \text{width}(A) \times \text{height}(A) \quad (4)$$

Here $\text{width}(A)$ is the set of all indices that index into width axis of A (i.e., the elements of width on which the partial map A is defined), and we consider this as a disjoint set from the analog set $\text{height}(A)$. Hence there is no ambiguity as to which point $A_{x,y}$ corresponds to, and the order does not matter (i.e., $A_{x,y}$ is equal to $A_{y,x}$ and in both cases correspond to the value of A at the point where the width axis is x and the height axis is y). If we want x to index into the height axis of B instead of into the width axis then we need to explicitly *cast* it as is done in (4).

The *signature* of ROT , stated in (3), is that it maps a $\{\text{width}, \text{height}\}$ -type tensor into a $\{\text{width}, \text{height}\}$ -type tensor. If we feed into ROT a tensor A with an extra axis such as channel then it is considered a *dangling axis* which means that the axis channel is carried through to the output, which will be a tensor B of type $\{\text{width}, \text{height}, \text{channel}\}$, such that for every $c \in \text{channel}(A)$, $B_c = ROT(A_c)$. That is, the operation ROT is applied independently to every restriction of A to the coordinates where the channel axis equals c . Similarly, if we feed into a tensor A with type $\{\text{width}, \text{height}, \text{channel}, \text{batch}\}$ corresponding to a *batch* of images then the output type will be $\{\text{width}, \text{height}, \text{channel}, \text{batch}\}$, with ROT applied to every $\{\text{channel}, \text{batch}\}$ restriction independently.

1 Formal definitions

We now describe the formal definitions.

Axes. An *axis* is a set of the form $\{(\text{name}, x) | x \in X\}$ where name is a string and X is an ordered set. If we don't specify the ordered set X then it is assumed to be the set of natural numbers \mathbb{N} . Our convention is that that axes' names are strings of the form “type” or “type^{annotation}”, with the assumption that axes with names such as layer^{in} and $\text{layer}^{\text{out}}$ correspond to the same type of indices. The names are always unique, and we use the notation $\text{type}^{\text{annotation}}$ to denote the unique axis with name $\text{type}^{\text{annotation}}$. For $x \in X$, we use $\text{type}^{\text{annotation}}[x]$ to denote the corresponding element ($\text{type}^{\text{annotation}}, x$) in the set $\text{type}^{\text{annotation}}$. we use notation such as ax or $\text{ax}^1, \text{ax}^2, \dots$ to denote generic axes.

Tensors. A *tensor type* is a finite set $\mathcal{T} = \{\text{ax}^1, \dots, \text{ax}^d\}$ of axes. A (real-valued) *tensor* of type \mathcal{T} is a partial map $A : \text{ax}^1 \times \text{ax}^2 \times \dots \times \text{ax}^d \rightarrow \mathbb{R}$, where the set of coordinates (i_1, \dots, i_d) on which A is defined is a product set $I_1 \times \dots \times I_d$ where $I_j \subseteq \text{ax}^j$ for $j = 1 \dots d$. We write $A(i_1, \dots, i_d)$ or A_{i_1, \dots, i_d} for the corresponding coordinate. Since i_1, \dots, i_d are elements of disjoint sets, we can write the inputs to a tensor in any order without ambiguity. We denote the set I_j of coordinates of ax^j on which A is defined by $\text{ax}^j(A)$.

Partial assignments. If we supply a partial assignment $I = \{i_{i_1}, \dots, i_{j_\ell}\}$ to the axes $\text{ax}^{j_1}, \dots, \text{ax}^{j_\ell}$ with j_1, \dots, j_ℓ being distinct indices in $[d]$, then A_I is the tensor of shape $\mathcal{T}' = \mathcal{T} \setminus \{\text{ax}^{j_1}, \dots, \text{ax}^{j_\ell}\}$ that maps every $d - \ell$ set of indices $\{k_1, \dots, k_{d-\ell}\}$ which are elements of distinct axes in \mathcal{T}' into $A_{k_1, \dots, k_{d-\ell}, i_{i_1}, \dots, i_{j_\ell}}$. If $\mathcal{T} = \{\text{ax}^1, \dots, \text{ax}^d\}$ is a type then we let $\mathbb{R}^{\text{ax}^1, \dots, \text{ax}^d}$ denote the set of all tensors of type \mathcal{T} .

Operators. An *operator* is a (possibly partial) map that takes as input one or more tensors of a specified type, and outputs a tensor of a specified type. The *signature* of an operator is the types of tensors it takes as input and the type of tensor is output. If we invoke an operator F with k inputs on tensors A^1, \dots, A^k that contain axes not appearing in the signatures then the result is defined as follows. For every i , we let \mathcal{T}^i be the

set of axes that the i -th tensor contains and are missing from the corresponding part of F 's signature. For $F(A^1, \dots, A^k)$ to be defined we need that **(1)** none of those axes appear in the signature of the output, and **(2)** if an axis \mathbf{ax} appears in both \mathcal{T}^i and \mathcal{T}^j then it must hold that $\mathbf{ax}(A^i) = \mathbf{ax}(A^j)$. In this case, the output Y of $F(A^1, \dots, A^k)$ will have, in addition to the axes in its signature, also all the axes in $\mathcal{T}^1 \cup \dots \cup \mathcal{T}^k$. For every assignment I to these axes, Y_I equals $F(A_{\mathcal{T}^1=I}^1, \dots, A_{\mathcal{T}^k=I}^k)$ where by $A_{\mathcal{T}=I}$ we mean the restriction of A obtained by assigning to every \mathbf{ax} in \mathcal{T} the corresponding index in I .

Example: broadcasting. Consider the operator $ADD(x, y) = x + y$ whose signature is simply $ADD : \mathbb{R} \times \mathbb{R} \rightarrow \mathbb{R}$. If A is a $\{\text{row}, \text{col}\}$ tensor and B is a col tensor, then $ADD(A, B)$ will be defined if $\text{col}(A) = \text{col}(B)$ and in this case have type $\{\text{row}, \text{col}\}$. For every $i \in \text{row}(A)$ and $j \in \text{col}(A) = \text{col}(B)$, $ADD(A, B)_{i,j} = A_{i,j} + B_j$.

Preconditions and postconditions. An operator does not have to be defined on all tensors of a given type, and can have restrictions on the inputs, such as requiring certain inputs to have the same support, requiring the support to be a multiple of a certain number, etc. Since these restrictions can vary greatly in applications, these are not part of the signature of the operator, but rather can be stated as pre-conditions. Similarly, it is useful to state post-conditions on the various axes of tensors.

Dropping trivial dimensions convention. If a tensor A contains an axis \mathbf{ax} with $|\mathbf{ax}(A)| = 1$, we say that \mathbf{ax} is *trivial* in A . We make the convention that we do not distinguish between tensors that contain an axis trivially and ones that do not contain it at all. Hence we can add a trivial axis to make a tensor fit the signature of an operation, and we can drop one when we wish to align tensors. This means that for example we do not distinguish between a tensor A of type $\{\text{row}, \text{col}\}$ where $|\text{row}(A)| = 1$ and a tensor of type $\{\text{col}\}$: both are column vectors.

Casting. If A is a tensor containing axis \mathbf{ax} then $A_{\mathbf{ax} \rightarrow \mathbf{ax}'}$ is the tensor replacing \mathbf{ax} with \mathbf{ax}' . This transformation also changes the corresponding indices according to the semantic interpretation of the indices. So for example, $\text{channel} \rightarrow \text{layer}$ might map ('R', 'G', 'B') to (1, 2, 3). We can also cast multiple axes into one or vice versa, such as the flattening operations $A_{\{\text{width}, \text{height}, \text{channel}\} \rightarrow \text{layer}}$.

Slicing. If \mathbf{ax} is an axis of the form $\{(ax, x) | x \in X\}$ and $Y \subseteq X$ then $\mathbf{ax}[Y]$ is the subset of \mathbf{ax} defined as $\{(ax, x) | x \in Y\}$. Since X is well ordered, for every a, b we can use $\mathbf{ax}[a..b]$, $\mathbf{ax}[a..]$ or $\mathbf{ax}[..b]$ to denote the restrictions of \mathbf{ax} to the sets Y of inputs between a and b , at least a , or at most b respectively.¹
